(Received 26 January 2005; published 15 June 2005)

Ionization cross sections in collisions of antiprotons (\(\bar{p}\)) with \(\text{H}_2^+\) molecules are calculated for incident energies in the range of 2–500 keV by using a semiclassical impact-parameter method. The electronic motion is solved in a numerically accurate manner by means of a discrete variable representation. A sudden approximation is applied to the description of the molecular rotation and vibration. The present \(\bar{p}+\text{He}^+\) ionization cross sections are compared with the theoretical results of the ionization in \(\bar{p}+\text{He}^+\) and the experimental results of the production of \(\text{H}^+\) ions in \(\bar{p}+\text{H}_2\).

I. INTRODUCTION

The ionization of atoms and molecules by antiproton (\(\bar{p}\)) impacts has become the subject of great theoretical and experimental interest. A lot of elaborate calculations have been carried out for ionization in \(\bar{p}+\text{H}\) [1–14] and in \(\bar{p}+\text{He}\) [15–23], and have offered the single-ionization cross sections in agreement with the experimental results [24–29] for incident energies \(\bar{E}\approx 50\) keV. An interesting difference between the proton and antiproton impacts was experimentally recognized for the double-ionization cross sections of the He atom [24,25,28], and its origin could be explained by theoretical studies [15,27]. At low energies \((\bar{E}<50\) keV\)), however, there still remain large discrepancies between the experimental and theoretical results both for the single- and double-ionization processes. Measurements were further made for ionization in \(\bar{p}+\text{H}_2\) [28,30]. Again, a notable difference between the proton and antiproton impacts could be seen for the cross sections for production of the \(\text{H}^+\) ion. In a theoretical aspect, on the other hand, little is investigated about the ionization of molecules by antiproton impacts.

The aim of the present paper is to perform an elaborate calculation of the ionization process for molecular targets. Although the \(\text{H}_2\) molecule is the most desirable target for a detailed study, a reliable calculation of the two-electron system at \(\bar{E}=100\) keV is still laborious even for the simplest case of the He atom target. In this paper, hence we focus on the ionization process in the one-electron system \(\bar{p}+\text{H}_2^+\) — i.e.,

\[\bar{p}+\text{H}_2^+ \rightarrow \bar{p} + \text{H}^+ + \text{H}^+ + e.\]  

(1)

In the present case, the ionization of the \(\text{H}_2^+\) molecule results in, at the same time, its dissociation by Coulomb repulsion. For the description of the electronic motion, we employ the direct numerical solution based on discrete variable representation (DVR) [31–34], which was already applied to the same system for the calculations of the electronic excitation probabilities in collinear collisions [35,36] and of the three-dimensional adiabatic potential energy surface useful for an understanding of the protonium (\(\bar{p}p\)) formation mechanism [37,38].

For the molecular target, we must consider the rotational and vibrational degrees of freedom, which often prevent us from carrying out a complete theoretical calculation. Fortunately, the fact that the collision time is much shorter than the period of molecular rotation and vibration allows us to introduce a sudden approximation [39–41]. In this approximation, the internuclear distance and the molecular orientation remain fixed during the collision. The sudden approximation is commonly used for the calculation of electronic excitation in molecular collisions [42].

The present paper discusses the dependence of the ionization cross section on the internuclear distance and the molecular orientation, and reports the ionization cross section averaged over these quantities. Unfortunately, neither experimental measurements nor other theoretical calculations have been performed for ionization in \(\bar{p}+\text{H}_2^+\). Here, comparison is made with the calculation for \(\bar{p}+\text{He}^+\) [43] (\(\text{He}^+\) being the united atom limit of \(\text{H}_2^+\)) and with the measurement for \(\bar{p}+\text{H}_2\) [28].

II. THEORY

A. Impact-parameter method

A full quantum-mechanical calculation has now become possible as for ionization in the one-electron system of \(\bar{p}+\text{H}\) [14]. In the present case of incident energies \(\bar{E}>1\) keV, however, a semiclassical impact-parameter method is believed to be highly accurate. We can assume that the \(\bar{p}\) motion is given by a linear classical trajectory with a constant velocity \(V\). The incident energy in the laboratory frame is given by \(\bar{E}=\frac{1}{2}\mu V^2\), with \(\mu\) being the \(\bar{p}\) mass (equal to the \(p\) mass). The effect of trajectory bending due to the Coulomb force between the antiproton and target ion is negligible when \(\bar{E}>1\) keV [44]. Here and in the following, we use atomic units unless otherwise stated.

We introduce the space-fixed frame \((x,y,z)\), in which the \(z\) axis is chosen along the incident velocity and the \(\bar{p}\) trajectory lies on the \(xz\) plane (Fig. 1). The positions of the three heavy particles are described in Jacobi coordinates \((\text{R},\text{r})\). The distance \(R\) is given by \(R=\sqrt{b^2+V^2r^2}\), with \(b\) being the impact parameter and \(t\) the time. The polar and azimuthal angles of \(\text{r}\) are denoted by \((\theta, \phi)\). We also introduce the molecule-fixed frame \((x',y',z')\), in which the \(z'\) axis is chosen along the internuclear distance \(r\) (Fig. 1). Let \(s\) be the...
The time-dependent Schrödinger equation is
\[ i \frac{\partial}{\partial t} \Psi(s,t) = H \Psi(s,t). \]
Here, the Hamiltonian \( H \) is divided into two parts:
\[ H = H_0 + H_1, \]
where
\[ H_0 = -\frac{1}{2} \nabla^2 - \frac{1}{s_1} - \frac{1}{s_2} + \frac{1}{s_3} \]
is the electronic part and
\[ H_1 = -\frac{1}{\mu} \frac{\vec{r} \cdot \nabla}{r} + \frac{1}{|\vec{R} + \vec{r}/2|} - \frac{1}{|\vec{R} - \vec{r}/2|} \]
is related to the protons.

\[ \Psi(s,t) = \Psi(s,t) \exp(i \int dt' \tilde{H}(s,t')) \]

The electronic channels of the target molecule can be represented by the Born-Oppenheimer (BO) states. Defining \( \Psi_0(s,r) \) to be the BO wave functions with \( \lambda \) being the electronic magnetic quantum number and \( \alpha \) denoting the other electronic states, we give the initial condition
\[ \Psi(s,t = -\infty: \vec{r}) = \Psi_0(s:\vec{r}), \]
where \( (\alpha, \lambda) = (1,0) \) indicates the ground BO state. The \( \vec{r} \)-dependent probability of the transition \((1,0) \rightarrow (\alpha', \lambda')\) is defined as
\[ P(\alpha', \lambda': \vec{r}) = \left| \int \text{d}s' [\Psi_0^{(\alpha', \lambda')}(s: \vec{r})] \Psi(s,t = \infty: \vec{r}) \right|^2, \]
so that the \( \vec{r} \)-dependent ionization probability may be calculated from
\[ P_{\text{ion}}(r, \theta, \phi) = 1 - \sum_{\alpha' \lambda' \text{BS}} P(\alpha', \lambda': \vec{r}), \]
where the summation is taken over all electronic bound states (BS’s). The ionization probability becomes
\[ P_{\text{ion}} = \int |\chi_{\alpha}(r) Y_{\mu \nu}(\theta, \phi)|^2 P_{\text{ion}}(r, \theta, \phi) r^2 \sin \theta \text{d}r \text{d}\theta \text{d}\phi. \]

Since the probability (12) is evidently independent of the orientation of the impact parameter, the ionization cross section can be given by
\[ \sigma = 2 \pi \int P_{\text{ion}} \text{d}b. \]
For later convenience, we introduce the \( \vec{r} \)-dependent ionization cross sections

\[ \sigma_{\vec{r}} = 2 \pi \int P_{\text{ion}}(r, \theta, \phi) r^2 \sin \theta \text{d}r \text{d}\theta \text{d}\phi. \]
and accordingly the range of the integration over \( s \) the electronic continuum states, such as the total ionization distance \( ! \). We can average over \( j \) for the special case of \( f \) calculation of electronic excitation in molecular collisions This Franck-Condon approximation is often used for the calculation of electronic excitation in molecular collisions. It should be noted that the invariance for \( s \) is actually broken for the ionization process because the center of mass of \( H^+_2 \) is different from the midpoint of \( r \). It should be noted that the invariance for \( (\theta, \phi) \) \( \rightarrow (\theta, 2\pi - \phi) \) is valid only for the quantities integrated over the electronic continuum states, such as the total ionization probability \( (1) \).

If, for instance, \( r \) is always set to the mean internuclear distance \( \bar{r} = 2.05 \) a.u. like a rigid rotor or the \( r \) dependence of \( \sigma(\theta, \phi) \) is negligible, the ionization cross section can be evaluated by Franck-Condon-type approximation

\[
\sigma(\theta, \phi) = \sigma_{FC}(\theta, \phi) = \sigma(\bar{r}, \theta, \phi),
\]

and accordingly the range of the integration over \( \phi \) in Eqs. (12) and (16) can be reduced to \( 0 \leq \phi \leq \pi/2 \). The inversion symmetry is actually broken for the ionization process because the center of mass of \( H^+_2 \) is different from the midpoint of \( r \). It should be noted that the invariance for \( (\theta, \phi) \) \( \rightarrow (\theta, 2\pi - \phi) \) is valid only for the quantities integrated over the electronic continuum states, such as the total ionization probability \( (1) \).

This Franck-Condon approximation is often used for the calculation of electronic excitation in molecular collisions [42]. For the special case of \( j = 0 \) considered in the present study, we can average over \( \theta \) and \( \phi \) according to

\[
\sigma_{FC} = \frac{2}{\pi} \int_{0}^{\pi} d\theta \int_{0}^{\pi} \sin \theta d\theta \sigma_{FC}(\theta, \phi).
\]

C. Spheroidal coordinates

To describe the electronic motion in the \( \bar{r} + H^+_2 \) system, previous studies [36,37] introduced spheroidal coordinates \( (\xi, \eta, \gamma) \):

\[
\xi = -r + s_1 + s_2, \quad 0 \leq \xi < \infty,
\]

\[
\eta = \frac{s_1 + s_2}{r}, \quad -1 \leq \eta \leq +1,
\]

\[
\gamma = \gamma, \quad 0 \leq \gamma \leq 2\pi,
\]

which are adapted to the two-center Coulomb nature of the \( H^+_2 \) molecule. Since the antiproton has a negative charge, two-center attraction among the electron and the protons is the most important point to be considered in the numerical calculation.

Using the spheroidal coordinates, we can express the Hamiltonian \( H_0 \) as

\[
H_0 = \frac{2}{G} \left[ -\frac{\partial^2}{\partial \xi^2} + \frac{1}{4\xi^2} \frac{\partial^2}{\partial \eta^2} \right] - \frac{2}{\xi(2 + \xi)(1 - \eta^2)} \frac{\partial^2}{\partial \gamma^2} \sin \theta \partial \theta \partial \phi.
\]

where

\[
G(\xi, \eta) = \xi(2 + \xi) + r^2(1 - \eta^2).
\]

Splitting the wave function \( \Psi(\xi, \eta, \gamma) \) according to

\[
\Psi(\xi, \eta, \gamma) = \left( \xi(2 + \xi) \right)^{-1/2} \phi(\xi, \eta, \gamma, \gamma, \gamma),
\]

we have from the time-dependent equation (8)

\[
\frac{i}{\hbar} \frac{\partial \psi}{\partial t} = (T + U) \psi,
\]

where

\[
T = \frac{2}{G} \left[ -\xi(2 + \xi) \left( \frac{\partial^2}{\partial \xi^2} + \frac{1}{4\xi^2} \frac{\partial^2}{\partial \eta^2} \right) - \frac{2}{\xi(2 + \xi)(1 - \eta^2)} \frac{\partial^2}{\partial \gamma^2} \sin \theta \partial \theta \partial \phi \right]
\]

and

\[
U(\xi, \eta, \gamma) = \frac{4r + \xi}{2G(2 + \xi)} - \frac{1}{s_1} - \frac{1}{s_2} + \frac{1}{s_3}.
\]

We can show

\[
\frac{1}{s_1} + \frac{1}{s_2} = -\frac{4(r + \xi)}{G}.
\]

The distance \( s_3 \) can be evaluated from \( s_3 = |R - s| \) with use of expression (2). The explicit time dependence enters only through \( s_3 \) in the time-dependent equation (25).

III. NUMERICAL CALCULATIONS

A. Discrete variable representation

In the DVR method, the wave function is directly calculated on the grid points constructed from the zeros of orthogonal polynomials. The advantages of the DVR method are that the off-diagonal coupling matrix becomes sparse because it comes from only the kinetic energy terms, and in addition its matrix elements can be evaluated in purely algebraic form derived from the properties of orthogonal polynomials.

We use the generalized Laguerre polynomial \( L_{nM}^{(a+1)}(\xi) \) for the grid \( \xi_i \) (\( i = 1, 2, \ldots, N \)), the Legendre polynomial \( P_{nM}(\eta) \) for \( \eta_j \) (\( j = 1, 2, \ldots, M \)), and the Chebyshev polynomial of the first kind \( T_{n+2}^{(a+1)}(u) \) with the argument \( u = \cos(\gamma / 2) \) for \( \gamma \) which are adapted to the two-center Coulomb nature of the \( H^+_2 \) molecule. Since the antiproton has a negative charge, two-center attraction among the electron and the protons is the most important point to be considered in the numerical calculation.

Using the spheroidal coordinates, we can express the Hamiltonian \( H_0 \) as

\[
H_0 = \frac{2}{G} \left[ -\frac{\partial^2}{\partial \xi^2} + \frac{1}{4\xi^2} \frac{\partial^2}{\partial \eta^2} \right] - \frac{2}{\xi(2 + \xi)(1 - \eta^2)} \frac{\partial^2}{\partial \gamma^2} \sin \theta \partial \theta \partial \phi.
\]

where

\[
G(\xi, \eta) = \xi(2 + \xi) + r^2(1 - \eta^2).
\]

Splitting the wave function \( \Psi(\xi, \eta, \gamma) \) according to

\[
\Psi(\xi, \eta, \gamma) = \left( \xi(2 + \xi) \right)^{-1/2} \phi(\xi, \eta, \gamma, \gamma, \gamma),
\]

we have from the time-dependent equation (8)

\[
\frac{i}{\hbar} \frac{\partial \psi}{\partial t} = (T + U) \psi,
\]

where

\[
T = \frac{2}{G} \left[ -\xi(2 + \xi) \left( \frac{\partial^2}{\partial \xi^2} + \frac{1}{4\xi^2} \frac{\partial^2}{\partial \eta^2} \right) - \frac{2}{\xi(2 + \xi)(1 - \eta^2)} \frac{\partial^2}{\partial \gamma^2} \sin \theta \partial \theta \partial \phi \right]
\]

and

\[
U(\xi, \eta, \gamma) = \frac{4r + \xi}{2G(2 + \xi)} - \frac{1}{s_1} - \frac{1}{s_2} + \frac{1}{s_3}.
\]

We can show

\[
\frac{1}{s_1} + \frac{1}{s_2} = -\frac{4(r + \xi)}{G}.
\]

The distance \( s_3 \) can be evaluated from \( s_3 = |R - s| \) with use of expression (2). The explicit time dependence enters only through \( s_3 \) in the time-dependent equation (25).
the present calculation, the consideration of \((2L+1)\) grid points for the \(y\) coordinate means that the electronic angular momenta having \(|\ell| \leq L\) are actually included.

We expand the wave function \(\psi\) as

\[
\psi(\xi, \eta, \gamma, t; r) = \sum_{ijk} \psi_{ijk}(t; r)f_j(\xi)g_i(\eta)h_k(\gamma),
\]

where we have introduced the DVR basis functions

\[
f_j(\xi) = \left[ \frac{W(\xi)}{\omega_j} \right]^{1/2} L_N^{(1)}(\xi),
\]

\[
g_i(\eta) = \frac{P_M(\eta)}{\omega_i^{1/2}} \frac{dP_M(\eta)}{d\eta} \left[ \eta - \eta_i \right],
\]

\[
h_k(\gamma) = \frac{\omega_k^{1/2}}{2\pi} \sum_{\nu=-L}^{L} \cos[\nu(\gamma - \gamma_k)],
\]

with \(W(\xi) = \xi^{-\xi}\) being the weight function of \(L_N^{(1)}(\xi)\), \(\omega_j\) the quadrature weight of \(L_N^{(1)}(\xi)\) [45], \(\omega_i\) that of \(P_M(\eta)\) [45], and \(\omega_k = 2\pi/(2L+1)\). The DVR basis functions satisfy the following relations:

\[
f_j(\xi_j) = \left[ \frac{W(\xi_j)}{\omega_j} \right]^{1/2} \delta_{ij},
\]

\[
g_i(\eta_i) = \omega_i^{-1/2} \delta_{ij},
\]

\[
h_k(\gamma_k) = \omega_k^{-1/2} \delta_{kk},
\]

\[
\int_{-\infty}^{\infty} f_j(\xi)f_i(\xi)d\xi = \delta_{ij},
\]

\[
\int_{-1}^{1} g_i(\eta)g_j(\eta)d\eta = \delta_{ij},
\]

\[
\int_{0}^{2\pi} h_k(\gamma)h_k(\gamma)d\gamma = \delta_{kk},
\]

From Eqs. (33)–(35), the coefficients \(\psi_{ijk}\) in the expansion (29) turn out to be

\[
\psi_{ijk}(t; r) = \left[ \frac{\omega_i\omega_j\omega_k}{W(\xi_i)} \right]^{1/2} \psi(\xi_i, \eta_j, \gamma_k; t; r).
\]

Expression (29) substituted into Eq. (25) leads to time-dependent linear equations for \(\psi_{ik}(t)\):

\[
\frac{i}{\hbar} \partial \psi_{ik}/\partial t = \sum_{i'j'k'} T_{ijk,i'j'k'} \psi_{i'j'k'} + U(\xi_i, \eta_j, \gamma_k) \psi_{ijk},
\]

where the coupling matrix elements are

\[
T_{ij,k;i'j'k'} = -\frac{2\xi_i(2\xi_i + \xi_j)}{G(\xi_i, \eta_j)} \left[ \frac{\delta_{ij} \delta_{kk}'}{\delta_{ij'}} + \frac{1}{4\xi_i^2} \right]
\]

\[
\times f_j(\xi_i)g_i(\eta_j)h_k(\gamma)h_{k'}(\gamma)d\xi d\eta d\gamma.
\]

The integrals in this equation are evaluated in Refs. [32–34]. A set of \(N \times M \times (2L+1)\) coupled equations (40) is solved by a fourth-order Runge-Kutta method.

### B. Convergence behavior

The variations of the ionization cross section \(\sigma(r, \theta, \phi)\) with respect to \(L, M, \) and \(N\) are shown in Tables I–III. The internuclear distance \(r\) is fixed to be the equilibrium value (2.0 a.u.) of the \(H_2^+\) molecule. In Table I, a choice of \(L = 3\) for the grid points \(\gamma_k\) is seen to yield cross sections with relative errors \(|\Delta \sigma(r, \theta, \phi)/\sigma(r, \theta, \phi)| less than \(-2\%\) except for the case of \(\theta = 0\) at \(E = 100\) keV. Somewhat worse convergence for \(\theta = 0\) does not matter in the calculation of \(\sigma_\text{FC}\) since \(\sigma(r, \theta, \phi)\) is multiplied by the weight factor sin \(\theta\) in the integration over \(\theta\); cf. Eq. (16). For the convergence with respect to \(\eta_j\) (Table II), the relative errors of \(<2\%\) are produced when \(M \geq 6\) at the low energy \(E = 2\) keV and when \(M \geq 4\) at the high energies \(E \geq 10\) keV. Table III shows that, to obtain an accuracy of \(-2\%\) errors, we need \(N \geq 30\) or 40.

| Table I. Variation of the ionization cross sections \(\sigma(r, \theta, \phi)\) for \(\bar{p} + H_2^+\) in units of a.u., with respect to \(L\) at \(E = 2, 10, \) and 100 keV. The internuclear distance \(r = 2.0\) a.u., and the molecular orientations are \((\theta, \phi) = (\pi/2, 0)\) and \((0, 0)\). |
|-----------------|-----------------|-----------------|
| \(L\)          | \(E = 2\) keV   | \(E = 10\) keV  |

| 1              | 0.112           | 0.763           | 1.48            |
| 2              | 0.171           | 0.979           | 1.34            |
| 3              | 0.177           | 1.01            | 1.33            |
| 4              | 0.177           | 1.02            | 1.35            |
| \(\theta, \phi\) = (\pi/2, 0) | \(E = 100\) keV | \((20, 4)^a\)  |
| 1              | 0.564           | 1.44            | 2.26            |
| 2              | 0.524           | 1.35            | 1.62            |
| 3              | 0.501           | 1.30            | 1.41            |
| 4              | 0.495           | 1.28            | 1.31            |
| 5              | 1.27            |                | 1.27            |
| 6              | 1.25            |                | 1.25            |

\((N, M)\).
for $\xi_i$ at the low energies $E \leq 10$ keV and the smaller value $N=20$ at the high energy $E=100$ keV.

In the present calculation of the ionization cross sections, we chose the number of grid points $(N,M,L)=(35,6,3)$ for low energies ($E=50$ keV) and $(N,M,L)=(20,6,4)$ for high energies ($E>50$ keV). The total numbers of coupled equations to be solved are 1470 for $E=50$ keV and 1080 for $E>50$ keV.

### IV. RESULTS AND DISCUSSION

#### A. Dependence of the internuclear distance

We first examine the internuclear distance ($r$) dependence of the ionization cross section and ascertain the validity of the Franck-Condon (FC) approximation (18) or (19). Figure 2 shows the cross sections $\sigma(r, \theta, \phi)$ at $E=2$, 10, and 100 keV as a function of $r$ in the range where the $(v,j) = (0,0)$ state has a non-negligible radial distribution $r^2|\chi_{00}(r)|^2$ (cf. Fig. 3). The molecular orientations are chosen to be $(\theta, \phi) = (0,0)$, $(\pi/2,0)$, and $(\pi/2, \pi/2)$. For the orientation $(\pi/2, \pi/2)$, the cross section has very weak $r$ dependence. For the other orientations, the cross section increases with $r$ and takes much different values for the smallest and largest $r$ shown in the figure. As seen in Table IV, however, the FC result $\sigma_{FC}(\theta, \phi)$ are very close to $\sigma(\theta, \phi)$ for all the orientations. This can be easily understood by the fact that the cross section has roughly a linear dependence on $r$. Namely, if we can assume that

\begin{equation}
\sigma(r, \theta, \phi) = \sigma_{FC}(\theta, \phi) + \frac{d\sigma(\vec{r}, \theta, \phi)}{dr}(r-\vec{r})
\end{equation}

and further that $r^2|\chi_{00}(r)|^2$ is an even function of $r-\vec{r}$ (cf. Fig. 3) as in the case of harmonic oscillator, then the Franck-Condon approximation becomes accurate. Anyway, it is certain that the Franck-Condon approximation is very good for

Table II. Variation of the ionization cross sections $\sigma(r, \theta, \phi)$ for $\bar{p}+H_2^{+}$, in units of a.u., with respect to $M$ at $E=2$, 10, and 100 keV. The internuclear distance is $r=2.0$ a.u., and the molecular orientation is $(\theta, \phi)=(\pi/2,0)$.

the calculation of the $\vec{p} + \text{H}_2^+$ ionization cross sections. We use the Franck-Condon approximation to carry out the subsequent discussions.

B. Dependence of the molecular orientation

Figure 4 shows the ionization cross sections $\sigma_{FC}(\theta, \phi)$ as a function of the polar angle $\theta$ for some given azimuthal angles $\phi$ up to $\pi/2$. The quantity $(\sin \theta)\sigma_{FC}(\theta, \phi)$, plotted in the figure, directly indicates which angle $\theta$ is important in the integration over $\phi$. When $\phi = \pi/2$, the cross section becomes exactly a symmetric function of $\theta$ around $\theta = \pi/2$. The values of the cross section for $\phi > \pi/2$ can be evaluated by relation (17).

To see the preference of the polar angle $\theta$ for the ionization without respect to the $\phi$ dependence, we show the cross sections averaged over $\phi$, $\sigma_{FC}(\theta) = \int_0^{\pi} \sigma_{FC}(\theta, \phi) d\phi / \pi$, in Fig. 5 for $E = 2, 10, 50$, and $100$ keV. The cross section $\sigma_{FC}(\theta)$ is always symmetric around $\theta = \pi/2$. At low energies, we find that polar angles $\theta < \pi/2$ (or $> \pi/2$) are relatively more important in the ionization. At high energies, however, the peak position of $\sin \theta \sigma_{FC}(\theta)$ becomes $\theta = \pi/2$. Therefore, we can conclude that a molecular orientation perpendicular to the $\vec{p}$ incident direction is preferable for the ionization at high energies and the nonperpendicular (or possibly nearly parallel) orientations are at low energies.

For the $\phi$ dependence, the ionization cross sections averaged over $\theta$, $\sigma_{FC}(\phi) = \int_0^{\pi} \sigma_{FC}(\theta, \phi) d\theta / \pi$, are shown in Fig. 6 for $E = 2, 10, 50$, and $300$ keV. On the whole, the $\phi$ dependence is not so strong. We can find that small azimuthal angles $\phi \approx 0$ are more important for the ionization regardless of the energy. This simply implies that the ionization occurs more frequently as either of the protons becomes closer to the antiproton. At the intermediate energies ($E = 10 – 100$ keV), the ionization cross section takes relatively large values and varies with $\phi$ in some measure. At the lowest ($E = 2$ keV) and the highest ($E = 300$ keV) energies, where the cross sections become small, however, we have a very weak $\phi$ dependence.

C. Ionization cross sections

The present results of the ionization cross sections $\sigma_{FC}$ averaged over all the molecular orientations are displayed in

FIG. 4. Ionization cross sections $\sigma_{FC}(\theta, \phi)$ times $\sin \theta$ for $\vec{p} + \text{H}_2^+$ in units of a.u., as a function of the polar angle $\theta$. The azimuthal angles are $\phi = 0$, $\pi/4$, and $\pi/2$ for $E = 10$ keV and $\phi = 0$, $\pi/5$, and $\pi/2$ for $E = 50$ keV.

FIG. 5. Ionization cross sections $\sigma_{FC}(\theta) = \int_0^{\pi} \sigma_{FC}(\theta, \phi) d\phi / \pi$ times $\sin \theta$ for $\vec{p} + \text{H}_2^+$, in units of a.u., as a function of the polar angle $\theta$ at $E = 2, 10, 50$, and $100$ keV.
Since the $\text{H}_2^+$ molecule is regarded as being identical to the $\text{He}^+$ atom in the limit $r \to 0$, it is interesting to compare the present results with the ionization cross sections for $\tilde{p} + \text{He}^+$. The $\text{He}^+$ ionization cross sections calculated by Wehrman et al. [43] are also included in Fig. 7 and are much smaller than the present $\text{H}_2^+$ results. (Other recent calculations for $\tilde{p} + \text{He}^+$ [13,47–49] reasonably agree with the results of Wehrman et al.) As could be expected from Fig. 2, the ionization cross section would be the smallest for $r = 0$. This can also be understood from the fact that the vertical ionization potential $I$ of $\text{H}_2^+$ becomes small with increasing $r$: $I = 54.4$ eV for $r = 0$ (He$^+$), $\sim 30$ eV for $r \sim 2$ a.u., and $\approx 13.6$ eV for $r = \infty$ (H). A similar feature for ionization can be observed in a comparison between $\tilde{p} + \text{H}_2$ and $\tilde{p} + \text{He}$ [28].

For the ionization in $\tilde{p} + \text{He}$, Janev et al. [46] and later Wehrman et al. [43] suggested that the double ionization could be explained as a two-step sequential ionization process, and hence its cross section could be comparable to the single-ionization cross section for $\tilde{p} + \text{He}^+$. In the case of $\tilde{p} + \text{H}_2$, the double-ionization process produces the $\text{H}^+$ ion in the way

$$\tilde{p} + \text{H}_2 \to \tilde{p} + \text{H}^+ + \text{H}^+ + e + e.$$  \hspace{1cm} (43)

Since no data are available for the direct observation of Eq. (43), a comparison is made in Fig. 7 with the $\text{H}^+$ production cross sections for $\tilde{p} + \text{H}_2$ measured by Hvelplund et al. [28]. We can find that the present single-ionization cross sections for $\tilde{p} + \text{H}_2$ are very close to the $\text{H}^+$ production cross sections for $\tilde{p} + \text{H}_2$. This fact may imply that the $\tilde{p} + \text{H}_2$ double ionization can be explained in terms of the two-step sequential ionization as suggested by Janev et al. [46].

However, the $\text{H}^+$ ion can be produced in $\tilde{p} + \text{H}_2$ also through the dissociative ionization channel

$$\tilde{p} + \text{H}_2 \to \tilde{p} + \text{H} + \text{H}^+ + e.$$  \hspace{1cm} (44)

For electron or proton impacts on the $\text{H}_2$ molecule, the dissociative ionization occurs much more frequently than the double ionization [50,51]. It is not well understood whether this is also the case for the antiproton impacts [28,30]. To get some hint of the mechanism of the $\text{H}^+$ production in $\tilde{p} + \text{H}_2$, we plot in Fig. 8 the present $\tilde{p} + \text{H}_2$ results of the ionization probabilities $P_{\text{ion}}(\bar{r}, \theta, \phi)$ and the excitation probabilities $P_{\text{exc}}(\bar{r}, \theta, \phi)$ given by

$$P_{\text{exc}}(\bar{r}, \theta, \phi) = 1 - P(\alpha = 1, \lambda = 0; \bar{r}, \theta, \phi) - P_{\text{ion}}(\bar{r}, \theta, \phi).$$  \hspace{1cm} (45)

For the $\text{H}_2^+$ molecule, if the electronic excitation occurred vertically, the molecules in any electronic excited states would essentially dissociate ($\rightarrow \text{H} + \text{H}^+$) through the repulsive part of the potential energy curve [52]. Therefore, the excitation probability $P_{\text{exc}}$ may be the lower limit of the dissociation probability. (The dissociation can also take place through the momentum-transfer process within the electronic ground state.) Figure 8 shows that the excitation occurs much more frequently than the ionization. This means that if the assumption of the two-step sequential process were accurate, the $\text{H}^+$ ion would be produced rather through the dissociative ionization (ionization+excitation). The similarity between the ionization in $\tilde{p} + \text{H}_2^+$ and the $\text{H}^+$ production in $\tilde{p} + \text{H}_2$, found in Fig. 7, would be merely accidental. Further study is needed for an understanding of the $\text{H}^+$ production mechanism in $\tilde{p} + \text{H}_2$. In the present calculation, it might have been possible to obtain the cross sections for excitation in $\tilde{p} + \text{H}_2^+$. As seen in Fig. 8, however, the calculation, requir-
ing a wider range of impact parameters, would become extremely time consuming. Such a calculation remains in future work.

V. SUMMARY AND REMARKS

The most elementary ion-molecule collision system may be $\bar p + \text{H}_2^+$ because we can investigate the collision processes free of electron-correlation or electron-transfer effects. It is hence possible to carry out a considerably accurate calculation for this system. In the present study, the DVR method using spheroidal coordinates has been found useful. We have been able to produce the reliable ionization cross sections. Hopefully, measurements will be made soon for this system.

The internuclear distance and the molecular orientation dependence of the ionization cross section has been discussed in the framework of sudden approximation. The Frank-Condon approximation has been found to work very well for the rotational and vibrational ground state in the present system. To test the validity of the Frank-Condon approximation for rotational or vibrational excited states, we must investigate the $r$ dependence of $\sigma(r, \theta, \phi)$ for both smaller and larger values of $r$. Nevertheless, $\sigma(r, \theta, \phi)$ is still expected to be roughly approximated by a linear function (42) even if the related range of $r$ is somewhat wider than the present one. Probably, the Frank-Condon approximation will be good unless the rotational or vibrational state becomes very high.

The preference of the molecular orientation for ionization appears differently for low and high energies. The ionization cross section $\sigma(r)$ becomes large with the internuclear distance $r$. For the $\text{H}_2^+$ molecule, the mean internuclear distance $\bar r$ increases as the vibrational state becomes high. Hence, the Frank-Condon approximation says that the ionization cross section is larger for higher vibrational states. When the molecule is also in a rotational excited state, the mean internuclear distance becomes large owing to the centrifugal force. However, since the spherical harmonics are strongly dependent on $\theta$ for $j > 0$, the dependence of the ionization cross section on the rotational state cannot be easily conjectured.

As indicated in previous studies [35,36,53], when the energy is $\lesssim 1$ keV, the electronic excitation is negligible in the $\bar p + \text{H}_2^+$ collisions. In the region of such low energies, where $\bar pp$ formation and dissociation due to momentum transfer become the important reaction channels, the sudden approximation is of no use for the description of the molecular rotation and vibration, but alternatively the adiabatic (i.e., Born-Oppenheimer) approximation is fairly good for the electronic motion [35–37]. In the case of $\bar p + \text{H}_2$, however, the adiabatic approximation is invalid even at low energies [54]. A theoretical approach that can accurately treat the ionization process would be inevitable also for a physical understanding of $\bar pp$ formation in low-energy $\bar p + \text{H}_2$ collisions. The study of the $\bar p + \text{H}_2$ system is very interesting and challenging. Direct numerical solution of the time-dependent Schrödinger equation, like the present method, has now become possible for the two-electron system $\bar p + \text{He}$ [22]. In the near future, the development of computer ability will enable us to apply the present method to the calculation of the $\bar p + \text{H}_2$ collisions.
